Abstract

This paper estimates the causal effect of perceived job insecurity - i.e. the fear of involuntary job loss - on health in a sample of 22 European countries. We rely on an original instrumental variable approach based on the idea that workers perceive greater job security in countries where employment is strongly protected by the law, and relatively more so if employed in industries where employment protection legislation is more binding, i.e. in industries with a higher natural rate of dismissals. Using cross-country data from the 2010 European Working Conditions Survey, we show that when the potential endogeneity of job insecurity is not accounted for, the latter appears to deteriorate almost all health outcomes. After controlling for endogeneity, the health-damaging effect of job insecurity is confirmed for a subgroup of health outcomes, namely self-rated health, being sick in the past 12 months, suffering from skin problems, headaches or eyestrain and stomach ache. As for other health variables, the impact of job insecurity appears to be insignificant at conventional levels.

1 Introduction

There is evidence in the recent literature that losing one's job has health-damaging effects¹ which may go as far as inducing a higher risk of mortality.² Although job loss is a highly traumatizing event, it is fortunately not very frequent. In contrast, the *fear* of involuntary job loss, i.e. perceived job insecurity, is likely to be much more widespread and one may wonder whether its health impact is as negative as that of actual job loss.

This is an important question from a policy point of view since perceived job insecurity has increased in a large number of industrialized countries over the past twenty years. Following several downsizing episodes in the USA and in Europe, a widely shared view has developed according to which employment relationships have become more unstable than they used to be. Internal labor markets characterized by long careers within firms (Doeringer and Piore (1971)) have been undermined. Long-term employer-employee relationships have declined (Cappelli (1999); Givord and Maurin (2004)) and the labor market seems to have been increasingly working like a spot market (Atkinson (2001)). Correspondingly, the perception of job insecurity has developed in most OECD countries since the 1990s (OECD (2004)).

The importance of job insecurity for workers' well-being has been underlined in the literature. Böckerman et al. (2011) provides evidence of a strong negative impact of job insecurity on job satisfaction. This impact is actually much stronger than that of the actual type of work contract held by workers - permanent vs. temporary - (Bardasi and Francesconi (2004); Chadi and Hetschko (2013)). In a recent paper, Origo and Pagani (2009) show that the level of job satisfaction of workers who do not experience job insecurity³ is not statistically different whether they have a permanent or a temporary contract. In contrast, workers who feel that their job is insecure are significantly less satisfied than workers who do not, whatever their type of work contract.

As regards health, the literature in epidemiology, occupational psychology and public health has long suggested that job insecurity may be harmful because it increases stress (Sverke and Hellgren (2002)). Psychologists have indeed shown that the anticipation of a stressful event represents an equally important or even greater source of anxiety than the event itself (Lazarus and Folkman (1984)). Consistently, job insecurity appears to raise self-reported general and psychological morbidity but also sickness absence and health service use - see the review of the literature by Ferrie (2001). In particular, it is strongly associated with specific symptoms such as eyestrain, skin and ear problems, stomach and sleep disorders

¹See Eliason and Storrie (2009b), Eliason and Storrie (2009a) and Deb et al. (2011).

²See Sullivan and Von Wachter (2009) and Browning and Heinesen (2012).

³Workers are considered as *not* experiencing job insecurity if they report that it is not very likely or not at all likely that they lose their job in the next 12 months.

(Cheng et al. (2005)). It is also negatively correlated with mental health, as measured by a 30-item psychiatric morbidity scale and a subscale for depressive factors (Ferrie et al. (2005)).

However, evaluating the causal impact of job insecurity on health raises a challenge which requires an adequate identification strategy. Perceived job insecurity is indeed likely to be endogenous. If pessimistic individuals perceive higher job insecurity and, at the same time, report a lower health status, our results are likely to be biased. Reverse causality is also likely to be a concern if unhealthy individuals are more likely to be employed in insecure (or, on the contrary, more secure) jobs or if negative health shocks make individuals more likely to fear that they could be fired. In all cases, standard OLS or probit estimates will be biased and will only capture the mere correlation between health and job insecurity.

In this paper, we implement an original identification strategy based on an instrumental variable approach in order to estimate the causal effect of job insecurity on health in a sample of 22 European countries. We consider that workers are likely to feel more secure with respect to their job if living in a country where employment is strongly protected by the law, and relatively more so if employed in sectors where employment protection legislation (EPL) is more binding. We thus instrument perceived job insecurity by the stringency of the employment protection legislation in the country where the individual lives interacted with the natural rate of dismissals in the sector where she is employed. This instrument is valid if workers do not self-select into sectors-by-country on the basis of characteristics correlated with their health. We show that this condition holds so that our instrument is truly exogenous. Using cross-country data from the 2010 European Working Conditions Survey (European Foundation for the Improvement of Living and Working Conditions (2012)), we show that when the potential endogeneity of job insecurity is not accounted for, the latter appears to deteriorate almost all health outcomes (self-rated health, having been sick in the past 12 months, suffering from skin and back problems, muscular pain, headaches or eyestrain, stomach ache, depression or anxiety, overall fatigue and insomnia). When tackling the endogeneity issue by estimating an IV model, the health-damaging effect of job insecurity is confirmed for a subgroup of health outcomes, namely self-rated health, being sick in the past 12 months, suffering from skin problems, headaches or eyestrain and stomach ache. As for other health variables, the impact of job insecurity appears to be insignificant at conventional levels.

Our paper contributes to the existing literature in several ways. To our knowledge, we are the first to provide a causal estimate of the impact of perceived job insecurity on health. Most of the literature on this topic estimates mere correlations. Part of it focuses on “attributed” job insecurity as captured by atypical employment (i.e. temporary rather than permanent work contracts) and finds no association between temporary work and general

health, but a positive correlation with ill mental health (Bardasi and Francesconi (2004)). The largest strand in this literature deals with perceived job insecurity, as we do. A meta-analysis conducted by Sverke et al. (2002) on 72 papers shows that both physical and mental health are found to decrease as perceived job insecurity increases. However, the magnitude of the effects appears to be ambiguous. On Taiwanese data, Cheng et al. (2005) find that job insecurity is associated with poor self-rated health, with the coefficient being larger for men than for women and, among women, for those employed in managerial and professional occupations. Using a cross-national survey, László et al. (2010) find differences across countries: job insecurity is associated with poor health in the Czech Republic, Denmark, Germany, Hungary, the Netherlands and Poland while the correlation is insignificant in countries such as Austria, France, Greece, Italy, Spain and Switzerland. In all cases, these papers estimate multivariate linear or logistic models disregarding the possibility that job insecurity be endogenous. Mandal et al. (2011) use a different approach : they estimate a random-effect model arguing that lagged job insecurity is not endogeneous in their data. They find that subjective expectation of job loss is a significant predictor of depression among older workers aged 55 to 65 years old. A few papers take into account the fact that time-invariant omitted variables may bias their results and estimate fixed-effect models. Using such an approach on Australian data, Green (2011) finds that perceived job insecurity negatively affects mental health. On German data, Reichert and Tauchmann (2012) try to tackle endogeneity issues by instrumenting job insecurity by recent staff reductions in the company where the worker is employed. Thus doing, they show that employees who are concerned about losing their jobs are less psychologically healthy than those in secure jobs. One may however wonder whether staff reductions in the company are really uncorrelated with psychological health conditional on job insecurity, which is a necessary condition for their instrument to be exogeneous.

Another attempt to deal with endogeneity issues is made by Ferrie et al. (1995) in a study considering the health impact of in-firm changes potentially incurring job insecurity. The authors use the British Whitehall II sample and exploit the foreseen privatization of the Property Services Agency, which used to be part of the London-based civil service. More specifically, they use a difference-in-difference approach and compare the health outcomes of those workers who knew they would be affected by privatization and a control group of civil servants who knew they would not, before and after privatization was announced. This set-up allows them to estimate the effect of an exogenous shock on firm ownership and organization on health. The authors find major negative effects on a large range of health outcomes for men, whereas health-damaging effects appear to be milder for women. They interpret these results as providing evidence that job insecurity damages health since expected privatization must have been associated by civil servants to an increased risk of involuntary job loss. However, Ferrie et al. (1998) show that this very episode of privatization was associated with major organizational changes. More recent work by Rathelot and

Romanello (2012), considers the effect of an episode of major in-firm restructuration in French energy utilities. They find that these restructurations have a strong negative effect on mental health conditions of the civil servants employed in these companies. As a consequence, using anticipated privatization as an exogenous shock does not permit to identify the effect of rising job insecurity - as opposed to anticipated organizational changes - on health.

We improve with respect to this literature in two respects. First, using an IV strategy allows us to control for both time-invariant and time-varying omitted variables and/or reverse causality. Second, we are able to identify the causal impact of perceived job insecurity as opposed to any organizational change since our instrument is strongly correlated with the former while it has no reason to vary with firm organization.

The rest of the paper is organized as follows. Section 2 presents our empirical strategy. Section 3 describes the data that we use. Section 4 reports our results and Section 5 concludes.

2 Empirical Specification

We investigate the impact of perceived job insecurity on health. As a first step, we estimate the following model by a standard probit⁴:

$$Health_{ijs}^* = \alpha + \gamma JobIns_{ijs} + X_{ijs}\beta + D_j + D_s + u_{ijs} \quad (1)$$

where $Health_{ijs}^*$ denotes the latent health status of individual i in country j and industry s and is only observed as:

$$Health_{ijs} = \mathbb{1}_{\{Health_{ijs}^* > 0\}} \quad (2)$$

$JobIns_{ijs}$ denotes the perceived job insecurity of individual i in country j and industry s . X_{ijs} is a vector of individual and firm characteristics. D_j and D_s are respectively country and industry dummies and u_{ijs} is an error term.

In some specifications we control for working conditions and psychosocial environment characteristics. The former capture adverse physical working conditions. The latter include indicators of job strain (job pressure, decision latitude and skill discretion) consistent with the Job Demand Control Model proposed by Karasek (1979) as well as a measure of Effort-Reward Imbalance which may be an additional source of job strain according to Siegrist (1996). Both working conditions $WorkCond_{ijs}$ and psychosocial work environment $PsychoSoc_{ijs}$ are indeed likely to be correlated with health and perceived job insecurity. If jobs which are insecure are simply lousy jobs, they may also be characterized by bad working conditions and high job strain. In that case, omitting the latter two variables generates an upward bias in

⁴All health outcomes are binary variables. Further details are available in the data section.

the estimate of γ . In order to control for both physical working conditions and psychosocial work environment, we estimate the following equation :

$$Health_{ijs}^* = \alpha + \gamma JobIns_{ijs} + X_{ijs}\beta + \mu WorkCond_{ijs} + PsychoSoc_{ijs}\xi + D_j + D_s + v_{ijs} \quad (3)$$

However, perceived job insecurity $JobIns_{ijs}$ is likely to be endogeneous in which case the probit estimate of γ is inconsistent. Endogeneity may arise either from omitted variable bias or reverse causality. As job insecurity and health variables are both self-declared, our estimates are biased if pessimistic individuals systematically tend to report higher job insecurity and lower health status (and the reverse holds for optimistic individuals). Reverse causality is another potential source of bias if unhealthy individuals are more likely to be employed in more insecure (or more secure) jobs. This is also a concern if negative health shocks make individuals fear that they could be fired.

In order to overcome potential endogeneity problems, we rely on an instrumental variable approach. We estimate a probit model where $JobIns_{ijs}$ is assumed to be a continuous and endogeneous variable. The first-stage equation is:

$$JobIns_{ijs} = \delta EPRC_j * DR_{s,USA} + X_{ijs}\zeta + D_j + D_s + \eta_{ijs} \quad (4)$$

where $DR_{s,USA}$ is the dismissal rate in industry s in the USA and $EPRC_j$ denotes the employment protection legislation for regular contracts and collective dismissals in country j . In the second-stage, equation (??) is then estimated by a probit model where $\widehat{JobIns_{ijs}}$ substitutes for $JobIns_{ijs}$.

The intuition behind the choice of the instrument is the following. Perceived job insecurity $JobIns_{ijs}$ is likely to be higher in countries where employment protection legislation $EPRC_j$ is less stringent.⁵ The index for employment protection legislation is provided by the OECD - see Venn (2009) - and refers to the legislation regarding individual and collective dismissals of workers on regular labor contracts. A third component of overall employment protection legislation has to do with regulations of temporary work contracts. We do not include it in our EPL index (and restrict our sample accordingly to permanent workers) because it is not clear whether the rules restricting the use of temporary contracts actually protect temporary workers or rather permanent ones, by making temporary work either more

⁵In contrast, Clark and Postel-Vinay (2009) suggest that employment protection legislation is negatively correlated with the *satisfaction* with job security. According to them this negative correlation is due to the fact that their *satisfaction* variable captures two components of job security: the probability of job loss and the cost of it. The former decreases with EPL - which is consistent with our assumption - but the latter strongly rises with EPL since finding a new job is quite harder in countries where employment is strongly regulated.

costly or less convenient to use (Caroli et al. (2008)).

Of course, the stringency of employment protection legislation cannot be used, *per se*, as an instrument since its variability would be very low and it would capture all heterogeneity existing across countries. This is why we instrument job insecurity by the stringency of employment protection legislation $EPRC_j$ in the country where the individual lives interacted with the extent to which EPL is binding in the sector where the individual is employed. As is classical in the job and worker flow literature - see Bassanini et al. (2009) and Haltiwanger et al. (2013) - we consider that EPL is particularly binding in sectors where the natural rate of dismissal is high. We proxy the latter by the industry-level dismissal rate in the USA. The reason for choosing this country as a benchmark is that EPL is almost nonexistent in the USA - see Venn (2009) - so that the observed dismissal rates may be considered as capturing the natural dismissal propensity in the corresponding industries.

Overall, the assumption underlying our instrument is that workers living in countries with a strong employment protection legislation will feel comparatively more secure, as far as their job is concerned, when employed in industries with a high natural rate of dismissal because this is where the stringency of EPL makes more difference. Our identifying assumption is that workers do not self-select into sectors-by-country on the basis of characteristics which may be correlated with their health. We will provide evidence that this is not the case in Section 4.3.

Note that our instrument captures the risk of being dismissed which is likely to be a good predictor of the perceived risk of losing one's job, i.e. our job insecurity indicator. Finding a good instrument would have been more complicated should our variable of interest have been the individual's satisfaction with her job security. The latter is indeed likely to be determined not only by the risk of losing one's job, but also by the expected level of unemployment benefit and the probability of re-employment if dismissed. In the present case, our job insecurity variable captures the perceived risk of dismissal which is easier to predict since it does not depend on expectations about future well-being but only on the actual risk of dismissal faced by the individual.

3 Data

3.1 Presentation of the sample

We use the fifth wave of the European Working Conditions Survey (EWCS). Since its launch in 1990, the EWCS measures and monitors trends and changes in working conditions in Europe. It has been conducted every five years on a random sample of workers (salaried employees and self-employed) in a growing number of European countries (from 12 in 1990 to 34 in 2010).

The European Foundation for the Improvement of Living and Working Conditions commissioned the fifth wave of the EWCS to be carried out in winter-spring 2010. Face-to-face interviews were conducted with persons in employment in the 27 Member states as well as in Norway, Macedonia, Croatia, Turkey, Albania, Kosovo and Montenegro. The questionnaire covers issues such as employment status, and the general job context : working time, work organization, earnings and financial security, job insecurity, psychosocial work environment, work-life imbalance and access to training. It also covers several aspects of health and well-being, cognitive and psychological conditions as well as demographic and socio-economic characteristics.

In the 2010 wave almost 44,000 workers were interviewed across 34 European countries. The original sample included all persons aged 15 and above who were resident in the country that was being surveyed and who were in employment⁶ during the reference week.

Our empirical strategy uses the employment protection legislation index for individual and collective dismissals of workers on regular work contracts (EPRC). As this index is defined only for individuals employed with a regular contract in the business sector, we exclude from the sample self-employed individuals, individuals working in non-business sectors⁷, as well as individuals who did not have a regular work contract at the time of the survey. Furthermore, we exclude individuals working very short hours (less than 15 hours during the reference week). Finally, as the EPRC index was unavailable for 12 countries (out of 34), our final sample consists of 9,263 individuals across 22 countries.⁸

3.2 Variables

Perceived job insecurity is assessed by asking workers their opinion about the following statement : “I might lose my job in the next 6 months”. Five answers are available ranging from “strongly agree” to “strongly disagree”.⁹ We standardize job insecurity to mean 0 and 1 standard deviation.

⁶Being in employment was defined as having done any work for pay or profit during the reference week for at least one hour.

⁷For issues of data reliability, agriculture, mining and fuel are excluded too, so that the sectors included in our study correspond to sectors 15 to 74 in the NACE Rev. 1 classification.

⁸The EPRC index is available for the following countries : Austria, Belgium, the Czech Republic, Germany, Denmark, Spain, Finland, France, the United-Kingdom, Greece, Hungary, Ireland, Italy, the Netherlands, Norway, Poland, Portugal, the Slovak Republic, Sweden, Turkey, Slovenia and Estonia.

⁹This is a standard way to measure the feeling of job insecurity in the literature. For example, in the Karasek’s Job Content Questionnaire (JCQ), perceived job insecurity is measured on a 4-point scale by the proposition “My job is secure”, where response categories range from “strongly agree” to “strongly disagree” (Karasek et al. (1998)).

Measuring health using survey data is always a challenge. The EWCS questionnaire includes a question on self-rated health where respondents are asked to rate their health on a 5-point scale : very good, good, fair, bad or very bad. We dichotomize the responses into good (very good and good) and bad health (fair, bad or very bad).¹⁰ There is evidence in the literature that self-rated health is a good indicator of individual overall health (Ferrie et al. (1995)). It has been found to be a good predictor of mortality even after controlling for more objective measures of health (Idler and Kasl (1991); Idler and Benyamini (1997); Bath (2003)). However, the probability of reporting good or bad health may suffer from individual reporting heterogeneity (Etilé and Milcent (2006); Tubeuf et al. (2008)). This is why we also use more objective measures of health capturing specific diseases or symptoms. In the EWCS database, respondents are asked whether they suffered over the last 12 months from either skin problems, backache, muscular pain in shoulders, neck and/or upper limbs, muscular pain in lower limbs, headache or eyestrain, stomach ache, cardiovascular diseases, depression or anxiety, overall fatigue, or insomnia or general sleep difficulties. For each above-mentioned health disorder, we build a corresponding dummy variable taking value 1 if the individual suffered from it, 0 otherwise. We also exploit a question asking whether the individual worked when she was sick over the past 12 months : we build a binary variable indicating whether the respondent was sick over the past 12 months taking value 0 if the respondent answers “I was not sick” and value 1 otherwise.¹¹ This is a quite uncommon measure of health, which may however capture minor health problems or frail health potentially induced by job insecurity.

We also use some information on individuals’ well-being. We build a dummy variable equal to 1 if the individual answers “All the time”, “Most of the time” or “More than half of the time” to at least one of the following assertions : “[Over the past two weeks] I have felt cheerful and in good spirits”; “I have felt calm and relaxed”; “I woke up feeling fresh and rested”; “My daily life has been filled with things that interest me”. Our well-being dummy indicator is equal to 0 otherwise.

Our baseline specification includes a set of covariates capturing individual and firm characteristics. Some specifications also control for working conditions and psychosocial work environment.

Individual and firm characteristics include age (entered as a continuous variable), gender, the presence of a spouse or partner in the household, occupation¹² (managers and professionals,

¹⁰Alternatively, we also treat self-rated health as a continuous variable. However, this definition is not our preferred one since it makes the strong assumption that the impact of job insecurity is the same all along the health distribution.

¹¹Since this item is not available for Germany and Denmark, we have fewer observations in our models when we use it as a dependent variable.

¹²Based on the 1988 International Standard Classification of Occupations (ISCO 88).

technicians and supervisors, white collars, blue collars) and education¹³ (higher education, secondary education, below secondary). As the income variable in the EWCS has many missing values and is not quite reliable, we use a question on the “household’s ability to make ends meet given its total monthly income”. We build a dummy variable equal to 1 if individuals report that their household makes ends meet “with some difficulty”, “with difficulty” or “with great difficulty”, and equal to 0 otherwise. We interpret this indicator as a measure of households’ deprivation. We also use a question reporting whether the individual was unemployed immediately before this job (dummy variable equal to 1 if so, 0 otherwise), and information on the presence of an employee representative at the workplace (dummy variable equal to 1 if so, 0 otherwise).

Working conditions are captured by an index taking values 0 to 10, where 10 denotes adverse working conditions. It is the normalized sum of 15 dummy variables taking value 1 if the individual is exposed half of the time or more to a given working condition, and 0 otherwise. The 15 working condition components are : being exposed to vibrations from hard tools or machinery; to noise so loud that one would have to raise one’s voice to talk to people; high temperatures which make one perspire even when not working; low temperatures whether indoors or outdoors; breathing in smoke, fumes, powder or dust; in vapors such as solvents and thinners; handling or being in skin contact with chemical products or substances; breathing tobacco smoke from other people; handling or being in direct contact with materials which can be infectious, such as waste, bodily fluids, laboratory materials; having a job that involves tiring or painful positions; lifting or moving people; carrying or moving heavy loads; standing; performing repetitive hand or arm movements; handling angry clients or patients. As for psychosocial work environment characteristics, they are measured through a series of indicators adapted from the Job Content Instrument of Karasek (Karasek (1979)) and the Effort-Reward Imbalance Questionnaire (Siegrist (1996)). These indicators include job pressure, decision latitude, skill discretion and reward, and are measured as follows. Job pressure is built out of three components : not having enough time to get the job done (measured on a 5-point scale where response categories range from “always” to “never”), working at high speed (7-point scale ranging from “all the time” to “never”), and working to tight deadlines (7-point scale ranging from “all the time” to “never”). We combine the responses into a summary scale and normalize it to $[0;10]$, where 10 denotes high job pressure. We then divide the scale into tertiles, i.e low job pressure, moderate job pressure and high job pressure. A measure of decision latitude is obtained using three dummy variables : the ability to choose or change the order of tasks, the methods of work and the speed or rate of work (all variables taking value 1 if the individual has control over the corresponding decision, 0 otherwise). We combine the responses into a summary scale, normalize it to $[0;10]$, where 10 denotes high decision latitude, and divide it into tertiles. Skill discretion is measured by a single question asking whether one’s job involves learning new things (dummy variable

¹³Based on the International Standard Classification of Education (ISCED).

equal to 1 if so, 0 otherwise). Finally, workers' reward is assessed by two questions : being well paid to do one's work (measured on a 5-point scale where response categories range from "strongly disagree" to "strongly agree"); having a job that offers good prospects for career advancements (5-point scale ranging from "strongly disagree" to "strongly agree"). Responses are summed into a summary scale that is normalized to [0;10] and divided into tertiles.

3.3 Instrument

We instrument perceived job insecurity by the stringency of employment protection legislation EPRC in the country where the worker lives interacted with the US rate of dismissals in the industry where she is employed. We borrow US dismissal rates from Bassanini and Garnerio (2013). The database contains dismissal rates over 1996-2006 and uses an industry classification that can be matched, at a sufficiently disaggregated level, to the Nace Rev. 1 classification used in the EWCS. To capture the natural dismissal propensity at the industry level, we compute a quantitative indicator equal to the average US industry dismissal rate between 2000 and 2006.¹⁴ Overall, we have information on 23 industry-level US dismissal rates.

Data on employment protection legislation are provided by the OECD. The EPRC index that we use refers to the legislation regarding individual and collective dismissals of workers on regular labor contracts. As regards individual dismissals, it is built out of information on notification procedures, delays before the notice period can start, the length of the notice period and size of severance payments, the circumstances under which a dismissal is considered unfair and compensation and extent of reinstatement following unfair dismissal. Regarding collective dismissals, the index takes into account the number of workers above which dismissals are considered as collective as well as additional notification and delay requirements and other special costs to employers.¹⁵ The theoretical value of the EPRC index varies from 0 to 6 (where 6 is the most stringent legislation).¹⁶ The list of industries and countries that we use, together with the US sectoral dismissal rates and the national EPRC indices can be found in Appendix Tables A.3 and A.4.

¹⁴We assume that the natural dismissal propensity in the USA is stable over time and we average it over a complete cycle, 2000-2006.

¹⁵Further details on the construction of the employment protection index can be found in Venn (2009).

¹⁶The EPRC index that we use refers to year 2008. We pre-date it because, over the period under study, a number of EU countries implemented substantial reforms of employment protection legislation. Given that it takes a while for employees to understand how the new rules really work, people tend to base their expectations on prior information.

3.4 Descriptive statistics

Figure A.1 and Tables A.1, A.2 and A.3 provide the descriptive statistics for the full sample. As shown in Figure A.1, 31% of the workers strongly disagree with the statement that they might lose their job in the next six months, while 33% simply disagree, 19% neither agree nor disagree, 13% agree and 5% strongly agree. In the sample, the average age is 41 years old, and 59% of the individuals are men. 69% live with a spouse or partner, and 37% report having difficulties to make ends meet. 9% of individuals report having had a period of unemployment immediately before their current job, and 44% have an employee representative at their workplace. While 78% of individuals declare being in good health (good or very good self-rated health), we do see a number of health disorders. 47% of the workers report suffering from backache, 45% from muscular pain in upper limbs, 30% from muscular pain in lower limbs, 40% from headache or eyestrain, 37% from overall fatigue and 20% from insomnia or sleep difficulties. Overall, 94% of the individuals in our sample declare having been sick over the past 12 months. However, fewer workers report suffering from skin problems (8%), stomach ache (13%), cardiovascular diseases (5%), or depression or anxiety (10%). 92% of the individuals in the sample experienced well-being the week preceding the interview. We also control for the industry where the worker is employed. The largest proportions of respondents are found in retail trade (17%), renting and business activities (11%) and construction (11%). We also provide a country-by-country breakdown of our sample. Belgium, France and Germany are the most represented countries and Ireland is the country with fewest respondents.

4 Results

4.1 Probit estimates

Probit estimates of equations (??) and (??) are reported in Table 1.¹⁷ Each line presents the coefficient (resp. standard error) of perceived job insecurity ($\hat{\gamma}$) for a different health outcome.¹⁸ In column 1 we only control for individual and firm characteristics, i.e. age,

¹⁷Once conditioning on having no missing value on any dependent variable and/or covariate (including working conditions and psychosocial factors), our sample goes down to 8108 for all health outcomes - except for having been sick over the past 12 months (7041 observations).

¹⁸The coefficients and standard errors on individual and firm controls are reported in Appendix Table A.5 for one particular health outcome, namely self-rated health. As could be expected, age is negatively correlated with self-rated health. Male report better health than women and so do more educated people. Once controlled for education, occupation does not appear to be significantly correlated with health. Living with a spouse or partner, being unemployed immediately before the current job and the presence of employee representatives in the establishment do not seem to significantly affect self-rated health either. In contrast, having problems to make ends meet is associated with poorer self-rated health which is unsurprising if they capture to some extent low income levels.

gender, education, occupation, marital status, difficulties to make ends meet, period of unemployment immediately before current job, presence of employee representatives in the establishment where the person is employed, industry and country dummies. Job insecurity appears to be positively correlated with all health disorders in our data except cardiovascular diseases. In particular, it is associated with a long series of physical troubles (skin and back problems, muscular pain, headaches or eyestrain, stomach ache) as well as with depression or anxiety, overall fatigue and insomnia, all of these at the 1% significance level. Unsurprisingly, job insecurity is also associated with poorer self-rated health. Coefficients in Table 1 imply that when job insecurity increases by 1 standard deviation, the probability of reporting bad self-rated health increases by 4.2% on average in our sample.¹⁹ Job insecurity is also correlated with having been sick over the past 12 months, although more weakly (and at the 10% significance level only): a one-standard-deviation increase in job insecurity raises the probability of being sick by 0.5%. Beyond its health-damaging effect, we also find that job insecurity decreases the probability of reporting at least one dimension of well-being over the past two weeks (either feeling cheerful or relaxed or rested or having an interesting life). So, job insecurity appears to be uniformly harmful to health and to our measure of well-being.

Results are very similar when controlling for bad physical working conditions - see column (2). Whatever the health outcome or well-being variable we consider, the point estimate on job insecurity is slightly lower than when we do not include any indicator of working conditions. However, its magnitude remains in the same range as in column (1) and it is highly significant at conventional levels, except for cardiovascular diseases. The same pattern of results is also found when adding psychosocial factors to our specification - see column (3). A one-standard-deviation increase in job insecurity increases the probability of reporting bad self-rated health by 2.7%.²⁰

Overall, the results from these simple probit estimates are consistent with most findings in the literature suggesting that job insecurity is associated with ill physical and mental health and with lower well-being (Ferrie (2001)).

¹⁹Average marginal effects are computed by first calculating the marginal effect for each observation and then averaging over the entire sample.

²⁰The coefficients and standard errors on working conditions and psychosocial work environment characteristics are reported in Appendix Table A.5 for one specific health outcome - i.e. self-rated health. Unsurprisingly, bad working conditions deteriorate self-rated health. Moderate and, to a larger extent, low job pressure are associated with better health than high job pressure. As suggested by Siegrist (1996), higher rewards for given effort levels are important to workers' well-being and they appear to be correlated with better self-rated health. The same holds for high decision latitude which appears to be positively correlated with self-reported health.

4.2 IV estimates

However, as mentioned in section 2, job insecurity is likely to be endogenous both because of potential omitted variable bias and of reverse causality. In order to deal with this issue, we estimate a two-stage model in which $JobIns_{ijs}$ is instrumented by the stringency of employment protection legislation in the country where worker i lives interacted with the natural rate of dismissals in the industry where she is employed. Results from the first-stage estimates - see equation (??) - are reported in Table 2.²¹ As expected, we find that workers living in countries with more stringent EPL feel comparatively less insecure when employed in sectors characterized by a high natural rate of dismissals. When controlling for individual and firm characteristics only - column (1) -, the coefficient on the EPRC*Dismissal interaction is negative and significant at the 5% level. Results are, if anything, stronger when controlling for working conditions and/or psychosocial work environment - see columns (2) and (3).

Second-stage estimates confirm the damaging impact of job insecurity on a number of health outcomes²² - see Table 3. Results in column (1) show that job insecurity increases the probability of reporting poor self-rated health and this effect is significant at the 1% level.²³ Coefficients in Table 3 imply that when job insecurity increases by one standard deviation, the probability of reporting poor health increases by 21%. Job insecurity also increases the probability of having been sick over the past 12 months. Here again, the effect is highly significant (at the 1% level) : a one-standard-deviation increase in job insecurity raises the probability of being sick by 30%. Given the indirect way in which we have defined this variable²⁴, one has to be careful in interpreting the results. Nonetheless, the fact that our findings based on the use of this variable are consistent with those obtained for self-rated health is quite reassuring and suggests that job insecurity has a substantial negative impact on general health.

Our results also suggest that it raises the frequency of more specific health symptoms. When job insecurity increases by one standard deviation, the probability of reporting headaches and/or eyestrain indeed increases by 25%. The corresponding figures for skin problems and

²¹The coefficients and standard errors on all control variables are reported in Appendix Table A.6. All standard errors are clustered at the country*industry level.

²²All standard errors are clustered at the country*industry level.

²³Treating self-rated health as a continuous variable also yields a negative point estimate on job insecurity. However, it is not significant at conventional levels. This result may not be surprising since the model we estimate in this case hinges on the assumption that the impact of perceived job insecurity is constant along the self-rated health distribution, which may not be the case in our sample.

²⁴An individual is considered as not having been sick in the past 12 months if she spontaneously answered “I was not sick” to the question “Over the past 12 months, did you work when you were sick”. She was coded as having been sick otherwise (see section 3).

stomach aches are respectively + 21% and +19% (all coefficients are significant at the 1% level). These marginal effects are, in absolute value, substantially larger than those estimated by OLS. This is the combined outcome of the many potential sources of endogeneity in our model. Measurement error may be one of those. Another source of endogeneity may also arise from unhealthy individuals self-selecting into more secure jobs.

Overall, job insecurity seems to have a negative impact on general health as well as more specific symptoms such as skin problems, headaches or eyestrain and stomach ache. These findings are robust to controlling for working conditions and/or psychosocial work environment: the point estimates remain stable across specifications although their magnitude slightly declines when including the most complete list of controls - see column (3). In contrast, for well-being, results get more significant when including additional controls: the impact of job insecurity is not significant when controlling only for individual and firm characteristics - see column (1) -, while it becomes significant at the 10% level when controlling for working conditions and at the 5% level when adding in psychosocial factors.

Concerning the other health dimensions, the impact of job insecurity is less clear. The second-stage coefficients are not statistically significant. However, given that IV estimates tend to be more imprecise than naive probit estimates, one has to be cautious in interpreting these results. A conservative interpretation of our findings is that job insecurity has clear damaging effects as regards general health, skin problems, headaches or eyestrain, stomach ache, as well as general well-being. In contrast, its causal effect on muscular pain, backache, depression and anxiety, insomnia and overall fatigue is much more uncertain.

4.3 Robustness checks

One may worry that unhealthy workers might self-select into low-dismissal industries and that this selection pattern may vary according to country-specific levels of EPL. If this were the case, our instrument would no longer be valid since the identifying assumption - according to which workers do not self-select into sectors-by-country on the basis of a characteristic correlated with health - would not hold anymore. In order to test for this, we estimate the following equation:

$$HighDismiss_{ijs} = \alpha + \beta Health_{ijs} + \gamma Health_{ijs} * EPRC_j + X_{ijs}\zeta + D_j + \eta_{ijs} \quad (5)$$

where *HighDismiss_{ijs}* is a dummy variable equal to 1 if worker *i* is employed in a high-dismissal industry and 0 otherwise. Other variables are defined as in Section 2. We use different definitions of high-dismissal industries: industries with dismissal rates higher than (i) the median, (ii) the third quartile and (iii) the upper decile. Whatever the threshold we

use for defining high-dismissal industries and whether or not we control for job insecurity in the regression, $\hat{\gamma}$ is never significant at conventional levels.²⁵ This suggests that workers do not self-select into industries on the basis of their health status in a different way according to the level of EPL in their home country. So, our instrument appears to be orthogonal to health and is hence valid to uncover the causal impact of job insecurity on health.

Another concern has to do with potential selection bias. If high-dismissal industries tend to rely more on temporary contracts in high-EPL countries in order to meet their needs in terms of labour force turnover, a disproportionate part of their workforce will be left out of our sample to the extent that we exclude temporary workers. If unhealthy workers are more likely to be employed on temporary contracts than healthy ones, workers employed in high-dismissal/high-EPL sectors*countries in our sample are likely to enjoy a better health status than those employed in high-dismissal/low-EPL sectors*countries. To the extent that our instrument predicts a lower job insecurity for workers employed in high-dismissal/high-EPL sectors*countries, we may overestimate the negative health impact of job insecurity. We check that the probability of being employed on a temporary contract is not higher in high-dismissal/high-EPL sectors*countries than in high-dismissal/low-EPL sectors*countries. When regressing our temporary contract variable on the $EPRC_j*DR_{s,USA}$ interaction²⁶, the coefficient on this interaction is insignificant with a point estimate of -.019 (standard error : 0.05), which suggests that our results are unlikely to be driven by selection bias due to the exclusion of temporary workers.

Our results derive from estimates run on a sample of workers aged 15 years old and above. However, senior workers may overreact to job insecurity since in most countries, their probability to get back to employment if dismissed is lower than for younger workers (OECD (2011)). In this case one could be afraid that our results be driven by a particularly strong effect of job insecurity on health for this specific age group. We check that our findings are robust to the exclusion of older workers by re-running our complete IV estimates²⁷ on the group of prime-age workers (aged 25 to 59). The results are virtually unchanged except that job insecurity also raises the probability of insomnia and/or general sleep difficulties at the 5% level in this sample.²⁸

²⁵When high-dismissal industries are defined as industries with dismissal rates higher than the median, the point estimate of $\hat{\gamma}$ is -0.011 - with standard error 0.048 - when controlling for firm and individual characteristics along with working conditions and psychosocial factors. When adding job insecurity as an additional control, the point estimate of $\hat{\gamma}$ is 0.001 with standard error 0.048.

²⁶This specification includes controls for individual and firm characteristics together with working conditions and psychosocial factors, as well as country and industry dummies.

²⁷This specification includes controls for individual and firm characteristics together with working conditions and psychosocial factors, as well as country and industry dummies.

²⁸The point estimates (resp. standard errors) are -0.893(0.169) for self-rated health, 0.867(0.227) for skin problems, 0.690(0.246) for headaches and eyestrain, 0.820(0.246) for stomach ache, 1.039(0.052) for being sick in the past 12 months and -0.756(0.326) for our well-being indicator. As for insomnia and sleep difficulties

Controlling for a measure of income when explaining individual health differences is standard in the literature (Lundborg (2013)). Given the scarce quality of income data in the European Working Conditions Survey, we use information on “problems to make ends meet” as an alternative in our baseline specification. However, one could be concerned that this variable might be endogenous if unhealthy workers have got problems making a living. In order to make sure that this does not generate a bias in our estimates, we re-estimate our complete IV specification dropping this covariate. The results are essentially unaffected.²⁹

5 Conclusion

In this paper, we provide a causal estimate of the effect of perceived job insecurity on various health outcomes in 22 European countries. We instrument perceived job insecurity by the stringency of employment protection legislation in the country where the individual lives interacted with the natural rate of dismissals in the industry where she is employed. Using cross-country data from the 2010 European Working Conditions Survey, we show that when the potential endogeneity of job insecurity is not accounted for, the latter appears to deteriorate almost all health outcomes (self-rated health, having been sick in the past 12 months, suffering from skin and back problems, muscular pain, headaches or eyestrain, stomach ache, depression or anxiety, overall fatigue and insomnia). When tackling the endogeneity issue by estimating an IV model, findings are more mixed. The health-damaging effect of job insecurity is confirmed for a subgroup of health outcomes, namely the probability of reporting poor health, being sick in the past 12 months, suffering from skin problems, headaches or eyestrain and stomach ache. In contrast, the impact of job insecurity on other health variables comes out as insignificant. Our results are robust to controlling for individual and firm characteristics but also for adverse working conditions and psychosocial environment characteristics.

Our findings suggest that the fear of involuntary job loss has clear worsening effects on a series of health disorders. The lack of significant impact on other health outcomes has to be interpreted with caution. IV estimates tend to be more imprecise indeed than naive probit estimates. So, a conservative interpretation of our findings is that job insecurity has clear damaging effects as regards general health, skin problems, headaches or eyestrain, stomach ache as well as general well-being. In contrast, its causal effect on muscular pain, back ache, depression and anxiety, and insomnia and overall fatigue is more uncertain.

they are 0.687(0.336).

²⁹The point estimates (resp. standard errors) of the job insecurity variable are -0.846(0.208) for self-rated health, 0.854(0.241) for skin problems, 0.787(0.199) for headaches and eyestrain, 0.780(0.274) for stomach ache, 1.037(0.044) for being sick in the past 12 months and -0.759(0.359) for our well-being indicator.

The strong health-damaging effects that we find for a number of health outcomes raises the issue of the mechanisms through which perceived job insecurity affects both mental and physical health. The psychology literature has long emphasized the role of stress. Another (complementary) explanation might be that workers who are afraid of losing their job tend to increase precautionary savings and hence reduce investments, in particular in health. The lack of information about health consumption in our data does not allow us to test such a hypothesis. However, investigating the consequences of job insecurity for health investments would be extremely valuable and improve our understanding of the mechanisms through which the fear of job loss deteriorates health.

Whatever the mechanism through which perceived job insecurity affects health, this effect is likely to be stronger for workers with low employability, i.e. with a low probability of finding a new job if losing the current one. According to Green (2011) employability is indeed a key determinant of the impact of job insecurity upon job satisfaction. The EWCS contains rough information on employability: workers are asked whether they feel that it would be easy for them to find a new job of similar salary if they were to lose/quit their current job. We define a dummy variable equal to 0 if they disagree or strongly disagree with this statement and 1 otherwise. If splitting our sample according to this proxy of employability and running our IV estimates, we find that job insecurity has a much stronger effect on health for low-employability workers than for high-employability ones. Specifically, in the low-employability group, job insecurity raises the probability to report skin problems, headaches or eyestrain, stomach ache, depression or anxiety, insomnia or sleeping problems and being sick over the past twelve months; it also significantly reduces well-being.³⁰ In contrast, in the high-employability group, job insecurity is mostly insignificant: the only effect it has is to deteriorate self-rated health and increase the probability of being sick over the past 12 months.³¹ These results can only be considered as suggestive given that our employability measure is highly subjective and hence likely to be endogenous. A promising avenue for future research would consist in investigating the potential role of employability on the health-damaging effects of perceived job insecurity using more objective measures of

³⁰All coefficients are significant at conventional levels. More specifically, when job insecurity increases by one standard deviation, the probability of reporting skin problems increases by 22%. The corresponding average marginal effects for headaches/eyestrain, stomach ache, depression/anxiety, insomnia/sleeping problems, and having been sick over the past 12 months are respectively +27%, +23%, +23%, +21%, and +27%. A one-standard-deviation increase in job insecurity also decreases the probability of experiencing well-being by 20%. Surprisingly, despite the fact that job insecurity increases depression symptoms and insomnia for low-employability workers, these report lower overall fatigue (the corresponding average marginal effect is equal to 21%). However, this effect is only significant at the 10% confidence level and is not easy to interpret given the imprecise content of the concept of overall fatigue used in the questionnaire.

³¹All coefficients are significant at conventional levels. When job insecurity increases by one standard deviation, the probability of reporting poor self-rated health increases by 25% and the probability of being sick by 31%.

employability.

| Depression, anxiety | .671 (.543) | .710 (.496) | .677 (.451) |
| Overall fatigue | -.460 (.477) | -.378 (.511) | -.299 (.461) |
| Insomnia, sleep difficulties | .541 (.495) | .573 (.467) | .555 (.410) |
| Well-being | -.719 (.456) | -.754* (.410) | -.745** (.370) |
| Observations | 8108 | 8108 | 8108 |
| Sick past 12 months | 1.051*** (.034) | 1.052*** (.035) | 1.049*** (.049) |
| Observations | 7041 | 7041 | 7041 |

Notes : (1) *** : significant at the 1% level, ** : significant at the 5% level, * : significant at the 10% level. (2) Standard errors in parentheses clustered at the country*industry level. (3) Base-line specifications include controls for individual and firm characteristics: age, gender, education, occupation, marital status, difficulties to make ends meet, period of unemployment immediatly before this job, presence of an employee representative in the establishment where the person is employed, industry and country dummies. (4) Working conditions is a summary indicator of 15 adverse working conditions. (5) Psychosocial factors include job pressure, decision latitude, skill discretion and reward.

Table A.1: Descriptive statistics : Individual and firm characteristics, working conditions and psychosocial factors.

| | Mean | Standard deviation |
|---|-------|--------------------|
| | (1) | (2) |
| Job insecurity (standardized) | 0 | (1) |
| Age | 40.75 | (10.96) |
| <i>Gender</i> | | |
| Male | .59 | (.49) |
| Female | .41 | (.49) |
| <i>Education</i> | | |
| Higher education | .30 | (.46) |
| Secondary education | .66 | (.47) |
| Below secondary | .04 | (.21) |
| <i>Occupation</i> | | |
| Managers and professionals | .16 | (.36) |
| Technicians and supervisors | .15 | (.36) |
| White collars | .31 | (.46) |
| Blue collars | .38 | (.49) |
| <i>Marital status</i> | | |
| Lives with a spouse or partner | .69 | (.46) |
| Difficulties to make ends meet | .37 | (.48) |
| Period of unemployment immediatly before this job | .09 | (.28) |
| Presence of an employee representative | .44 | (.50) |
| Bad working condition index (0 to 10) | 2.86 | (2.64) |
| Job pressure index (0 to 10) | 4.34 | (2.46) |
| Decision latitude index (0 to 10) | 6.47 | (3.95) |
| Reward index (0 to 10) | 4.85 | (2.34) |
| Skill discretion | .69 | (.46) |
| Observations | 8108 | 8108 |

Notes : (1) Standard deviations in parentheses.

Table A.2: Descriptive statistics : Health variables.

| | Mean | Standard deviation |
|------------------------------|------|--------------------|
| | (1) | (2) |
| Good self-rated health | .78 | (.42) |
| Skin problems | .08 | (.28) |
| Backache | .47 | (.50) |
| Muscular pain in upper limbs | .45 | (.50) |
| Muscular pain in lower limbs | .30 | (.46) |
| Headache, eyestrain | .40 | (.49) |
| Stomach ache | .13 | (.34) |
| Cardiovascular diseases | .05 | (.21) |
| Depression, anxiety | .10 | (.30) |
| Overall fatigue | .37 | (.48) |
| Insomnia, sleep difficulties | .20 | (.40) |
| Well-being | .92 | (.27) |
| Observations | 8108 | 8108 |
| Sick past 12 months | .94 | (.23) |
| Observations | 7041 | 7041 |

Notes : (1) Standard deviations in parentheses. (2) All variables are binary so that the mean can be interpreted as the average frequency in the sample.

Table A.3: Descriptive statistics : Countries and industries.

| Country | Frequency(%) | Industry | Frequency(%) |
|-----------------|--------------|------------------------------------|--------------|
| Austria | 3.87 | Food and beverages | 4.22 |
| Belgium | 12.77 | Textiles, wearing app. and leather | 2.82 |
| Czech Republic | 3.32 | Wood and wood products | 0.96 |
| Denmark | 4.21 | Paper, printing and publishing | 2.13 |
| Estonia | 3.58 | Chemicals and chemical products | 2.00 |
| Finland | 3.82 | Rubber and plastics | 1.21 |
| France | 11.21 | Non-metallic mineral products | 1.07 |
| Germany | 9.46 | Basic metals and fabricated metal | 3.95 |
| Greece | 2.32 | Machinery | 2.48 |
| Hungary | 3.91 | Electrical and optical equipment | 2.49 |
| Ireland | 2.22 | Transport equipment | 2.53 |
| Italy | 4.85 | Manufacturing, recycling | 2.29 |
| Netherlands | 2.65 | Electricity, gas and water supply | 1.70 |
| Norway | 3.48 | Construction | 10.50 |
| Poland | 3.89 | Motor trade and repair | 3.93 |
| Portugal | 3.37 | Wholesale trade | 5.12 |
| Slovak Republic | 3.18 | Retail trade | 17.44 |
| Slovenia | 4.28 | Hotels and restaurants | 6.25 |
| Spain | 3.32 | Transport and storage | 7.05 |
| Sweden | 3.13 | Post and telecommunications | 1.63 |
| Turkey | 2.64 | Financial intermediation | 5.69 |
| United Kingdom | 4.54 | Real estate activities | 1.20 |
| | | Renting and business activities | 11.33 |
| Observations | 8,108 | | 8,108 |

Table A.4: Employment Protection Legislation Index (EPRC) in Europe (2008) and industry-level US dismissal rates (mean value for 2000-2006).

| Country | EPRC index | Industry | US dismissal rate |
|-----------------|------------|------------------------------------|-------------------|
| Austria | 2.62 | Food and beverages | 2.83 |
| Belgium | 2.42 | Textiles, wearing app. and leather | 6.06 |
| Czech Republic | 2.79 | Wood and wood products | 5.16 |
| Denmark | 2.06 | Paper, printing and publishing | 3.61 |
| Estonia | 2.69 | Chemicals and chemical products | 3.22 |
| Finland | 2.23 | Rubber and plastics | 3.28 |
| France | 2.37 | Non-metallic mineral products | 3.47 |
| Germany | 3.21 | Basic metals and fabricated metal | 4.08 |
| Greece | 2.59 | Machinery | 4.76 |
| Hungary | 2.19 | Electrical and optical equipment | 5.93 |
| Ireland | 1.82 | Transport equipment | 3.08 |
| Italy | 2.66 | Manufacturing, recycling | 4.58 |
| Netherlands | 2.80 | Electricity, gas and water supply | 1.78 |
| Norway | 2.43 | Construction | 5.09 |
| Poland | 2.51 | Motor trade and repair | 2.67 |
| Portugal | 3.52 | Wholesale trade | 3.80 |
| Slovak Republic | 2.86 | Retail trade | 2.98 |
| Slovenia | 3.07 | Hotels and restaurants | 2.99 |
| Spain | 2.65 | Transport and storage | 3.35 |
| Sweden | 3.11 | Post and telecommunications | 4.16 |
| Turkey | 2.51 | Financial intermediation | 2.56 |
| United Kingdom | 1.62 | Real estate activities | 2.06 |
| | | Renting and business activities | 4.19 |
